FINAL TECHNICAL REPORT SPOKANE RIVER INSTREAM FLOW STUDIES

Prepared for

Spokane County Public Works Department and WRIA 54 & 57 Watershed Planning Units

Prepared by

1155 N. State St., Suite 700 Bellingham, WA 98225

May 2007

ACKNOWLEDGMENTS

Funding for this project has been provided by the WRIA 54 and WRIA 57 Planning Units through the Spokane County Public Works Department using the following grants: Washington Department of Ecology (Ecology) 2514 Watershed Planning Program, Ecology Instream Flow Supplemental, Ecology Water Resources Grant. Members of the WRIA 54 & WRIA 57 Instream Flow Technical Team have provided valuable time, input, and decisions throughout the duration of this study.

Thanks to Tim Vore and Avista Utilities who supplied valuable aerial photographs of the river as well as much local knowledge and flow adjustment of the river when possible.

Special thanks are due to the people who assisted in various ways on this study. Local landowners, particularly the Spokane Rifle Club, were very cooperative in allowing field teams to access their property for study purposes. Thanks to the Spokane Sheriff's Department for access to restricted river launches. The staff at Spokane County Public Works Department has been extremely helpful in many ways, particularly with field and technical support and coordinating communication with committees and involved parties.

EXECUTIVE SUMMARY

The Spokane River Physical Habitat Simulation (PHABSIM) Instream Flow study focuses on the fish habitat and instream flow needs of resident salmonids. Fisheries resources of primary concern in the Spokane River are game fish, including rainbow trout and mountain whitefish.

The study area was subdivided into two main Spokane River Instream Flow Study Areas (WRIA 57 and 54) and four tributaries: Spring, Little Chamokane, Coulee, and Deep creeks. The main Spokane River Study Areas encompass the mainstem from River Mile (RM) 63.8 at the upstream end of Nine Mile Reservoir to RM 73.8 at the Monroe Street Bridge near downtown Spokane. The river was further segmented into the WRIA 54 section, which extended from RM 63.8 to RM 72.3 at the mouth of Latah Creek, and the WRIA 57 section, which extended from RM 72.3 to RM 73.8. Five transects were selected for the study in WRIA 54 and two transects were selected in WRIA 57.

The mainstem Spokane River Instream Flow Study was conducted using the Physical Habitat Simulation (PHABSIM) modeling approach, which is commonly referred to as the U.S. Fish and Wildlife Service Instream Flow Incremental Method (IFIM). The tributary instream flow studies were conducted using the Toe-Width method developed by the US Geological Survey. Results of the PHABSIM study are contained in the main report. Results from the tributary Toe-Width study are contained in Appendix C.

A principal product of PHABSIM is the Weighted Usable Area (WUA) chart, which is a quantifiable index of habitat value, relative to flow. The modeled flow range in the mainstem Spokane River is from 350 cfs to 16,000 cfs. This report documents WUA results for rearing salmonids, including both rainbow trout and mountain whitefish. WUA results for spawning are reported for both species in WRIA 54 and only mountain whitefish in WRIA 57.

This report is organized into six main sections, 1.0 Introduction, 2.0 Methodology, 3.0 Results, 4.0 Hydrology, 5.0 Draft Recommendations and 6.0 References. The methodology, results, and hydrology are contained in the main body of the text and supporting technical data is located in the appendices.

PHABSIM ASSESSMENT GLOSSARY OF TERMS

Calibration Flow	Measured flow used to evaluate model (RHABSIM, PHABSIM) performance.
EESC	EES Consulting, Inc. Primary consultant for Spokane River PHABSIM study
Freshet	A sudden rise in the level of a stream, or a flood due to heavy rains or the rapid melting of
	snow and ice.
HABSIM	The Weighted Usable Area Habitat Simulation in RHABSIM.
HSC	Habitat Suitability Criteria- Values for depth, velocity, substrate and cover that reflect the
	likelihood that fish will use a particular range for each factor. HSC unique for each species
	and life stage of concern.
HYDSIM	The hydraulic model in RHABSIM.
IFIM	Instream Flow Incremental Methodology
PHABSIM	Analysis and integration of physical stream measurements and habitat preference criteria
	require the use of a group of computer programs developed by the US Fish and Wildlife
	Service. This set of programs is called Physical Habitat Simulation System (PHABSIM).
RCW	Revised Code of Washington
Redd	Most salmonids deposit their eggs in nests called redds. Redds are dug in the streambed
	substrate by the female. Most redds occur in predictable areas and are easily identified by
	an experienced observer by their shape, size, and color (lighter than surrounding areas
	because rocks have been overturned and biofilm and silt have been cleaned away).
	Mountain White Fish, also a salmonid, do not dig redds, but broadcast eggs into the river.
RHABSIM	PHABSIM is a suite of computer programs developed by the US Fish and Wildlife Service.
	EESC uses RHABSIM, a PC version of the original PHABSIM program, developed by
G: P 1	Tom Payne and Associates of Arcata, CA.
Stream Reach	A subset of the study area that is distinguished from other reaches for stated reasons.
Study Area	The portion of a river or stream that will be addressed in the study.
Study Site	A particular area within a Reach where transects are grouped.
VAF	Velocity Adjustment Factors (VAF) are a measure of how well the model simulates
	velocities using a three velocity set regression data set. A VAF between 0.90 and 1.10 is
	considered good. A VAF between 0.85 and 0.90 or between 1.10 and 1.15 is considered to
	be fair. A VAF between .80 and .85 or 1.15 and 1.20 is marginal, while a VAF below 0.80
WDFW	or above 1.20 is considered poor.
	Washington Department of Fish and Wildlife
Ecology	Washington Department of Ecology Water surface elevation
WSE	
WUA	Habitat quantification is expressed as an index called Weighted Useable Area (WUA), and
	is given in habitat per 1,000 linear ft of stream. WUA is the habitat rating (0.00-1.00) of
	the velocity multiplied by the habitat rating of the depth multiplied by the habitat rating of
	the substrate multiplied by the area of the cell, summed for all cells in the reach.

1.0 INTRODUCTION

1.1 Authority

EES Consulting, Inc. (EESC) conducted this study under contract to Spokane County and Tetra Tech, for the WRIA 54 and WRIA 55/57 Planning Units. This study was undertaken as part of the WRIA 54 & 55/57 Watershed planning processes administered by the Washington Department of Ecology (RCW 90.82).

This report is organized into five main sections; 1.0 Introduction, 2.0 Methodology and Approach, 3.0 Results, 4.0 Hydrology and 5.0 References. The methodology, results and hydrology are contained in the main body of the text and supporting technical data are located in the appendices.

1.2 Background

Two previous instream flow studies, focusing on different study areas and fish life stages, have been completed within the Spokane River watershed. One of these, "Instream Flow and Fish Habitat Assessment (Northwest Hydraulic Consultants and Hardin-Davis, Inc, 2004) overlaps slightly with the current study by employing a PHABSIM modeling approach to assess the relationship between streamflow and habitat potential on the mainstem Spokane River from the Post Falls Dam in Idaho, downstream to the confluence with Latah Creek. For most of the study area, spawning and rearing life stages were evaluated, however only spawning was assessed in the one-mile reach of WRIA 57 below the Monroe Street Bridge in Spokane.

A second study, conducted by Golder Associates (2003) utilized a wetted perimeter approach to evaluate the adequacy of established minimum instream flows in the Little Spokane River. Additional IFIM studies conducted in the basin include the Blue Creek IFIM and IFIM studies for fish and benthic invertebrates on Chamokane Creek.

This study focuses on the free-flowing portion of the Spokane River above Nine Mile Reservoir and below the Monroe Street Bridge in Spokane, spanning lower WRIA 57 and upper WRIA 54. The intent of doing additional work in WRIA 57 was to assess rainbow trout rearing habitat flow requirements (spawning needs were assessed in the aforementioned study). A PHABSIM modeling approach was employed to develop this assessment.

Additionally, photographs of several riffles in WRIA 57 and 54 were taken at different flows. The purpose of this photo documentation was to show the effect of different flow levels on the inundation of the riffle habitat. Sites included upstream and downstream of the Centennial Trail (Sandifur) bridge, upstream of the TJ Meenach Bridge, and downstream of the Gun Club. Selected photo documentation of the riffle habitat is presented in Appendix D.

An instream flow analysis was also conducted on four WRIA 54 tributary streams: Coulee, Deep, Little Chamokane, and Spring creeks. Toe-width methodology was used to develop estimates for preferred flows for rainbow trout rearing and spawning (Spring Creek only).

1.3 Study Objectives

Study objectives for the Spokane Instream Flow Studies were:

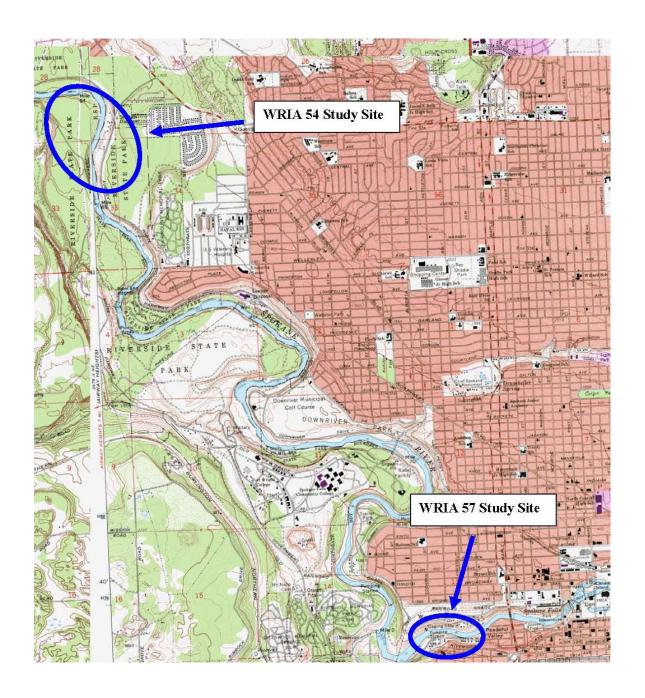

- Quantify the relationship between stream flow and available aquatic habitat for appropriate salmonid species and life stages for the free-flowing reach of the Spokane River above Nine Mile Reservoir.
- Quantify the preferred stream flow for trout rearing and spawning habitat, as appropriate, for Spring, Little Chamokane, Coulee and Deep creeks.
- Provide a well-documented, scientific basis to serve as a decision making tool for considering instream flow recommendations. Specifically, the areas of interest are the mainstem Spokane River from the backwater of Nine Mile Reservoir (RM 63.8), upstream to the Monroe Street Bridge at RM 73.8 and the four tributaries (Figure 1.3-1).

1.4 Spokane River Watershed

Originating as rainfall and snowmelt on the western flank of the Rocky Mountains, the headwaters of the Spokane River flow into Lake Coeur d'Alene in Idaho. The outlet to Lake Coeur d'Alene is partially controlled by a dam operated by Avista Utilities and water is stored in the lake on a seasonal basis. The drainage area of the Spokane River is approximately 4,290 square miles at the Spokane USGS gage site. Latah Creek, which enters the river approximately ½ mile downstream of the Spokane gage, provides a mean annual flow of 200 cfs from an additional 704 square mile watershed. The Spokane River Basin study area extends from RM 73.8, in Spokane (the Monroe Street bridge), downstream to the backwater of Nine Mile Reservoir. The gradient of the Spokane River within the study area is generally low and averages about 0.27% from Monroe Street downstream to Nine Mile Reservoir. Several higher gradient rapids can be found within this river segment.

The topography, hydrology and land use in the Spokane watershed are diverse. In the mountainous headwaters, much of the area is managed forest land with snow fields on the higher peaks and dense coniferous forests covering the mid-elevation slopes. The headwater streams are generally steep, while the upper and mid river segments generally wind along wider valley floors. The study area of this instream flow study is in a constricted valley with a mixed land use that is predominantly recreational park land along its banks. The banks of the river are mainly covered with boulders and cobble with some bedrock and minor areas of rip rap.

1.3-1 Spokane River IFIM Reach Map

2.0 METHODOLOGY AND APPROACH

The instream flow studies described in this report employed the following methodologies:

- PHABSIM mainstem Spokane River study areas
- Photo documentation of various flow over riffles (see section 1.2)
- Toe-Width WRIA 54 tributaries: Deep, Coulee, Little Chamokane, and Spring Creeks

The toe width portion of the study is described in Appendix C. The photo documentation of riffle habitat is presented in Appendix D. The remainder of this report focuses on the PHABSIM portion of the instream flow study.

2.1 Overview of PHABSIM Methodology

Unless otherwise noted, PHABSIM study procedures follow the WDFW/Ecology Instream Flow Guidelines (April, 2004). The PHABSIM methodology is based on the premise that stream-dwelling fish are more often found in a certain range of depths, velocities, substrates, and cover types, depending upon the species and life stage, and that the availability of these preferred habitat conditions varies with stream flow. PHABSIM is designed to quantify potential physical habitat available for each life stage of interest, for a target fish species, at various levels of stream discharge, using a series of modeling programs initially developed by the US Fish and Wildlife Service. Major components of the methodology include:

- Study site and transect selection
- Transect weighting
- Field collection of hydraulic data
- Hydraulic simulation to determine the spatial distribution of combinations of depths and velocities with respect to substrate and cover under a variety of discharges
- Habitat simulation, using habitat suitability criteria, to generate an index of change in habitat relative to change in discharge

The product of the habitat simulation is expressed as Weighted Usable Area (WUA) for a range of stream discharges. It is important to recognize that the product of a PHABSIM analysis is not a set value but a range of values to be used as a tool for discussing and determining a range of stream flows that will meet the needs of all affected resources.

2.2 Stream Description

The Spokane River Study Area extends from the upper end of the Nine Mile Reservoir (RM 63.8), upstream to the Monroe Street Bridge (RM 73.8). Rainbow trout and mountain whitefish utilize this area as a corridor for upstream and downstream movement, spawning and for both juvenile and adult rearing.

Within the mainstem Spokane River Study Area, the river is primarily contained in a single, confined channel. For short distances, the channel may split around islands or gravel bars and form distinct geomorphic features that exhibit habitat variations dissimilar from the main channel.

4

Differences in morphology and hydrology in the Spokane River were addressed by segmenting the river into two distinct reaches. Study reaches within the ten mile study area of the Spokane River were differentiated by changes in hydrology, slope and habitat type.

2.3 Stream Reach Description

WRIA 54 Reach (RM 63.8-72.3): The majority of the WRIA 54 Reach is characterized by moderate-gradient, long, wide glides with short sections of riffles, rapids and pools. Side and split channel areas comprise less than 8 % of the river length. The upper end of this reach, just downstream of Latah Creek and again near the T.J. Meenach Bridge, is less confined, with a few mid-channel bars and islands. Near the lower end of this reach, large bedrock features create several rapids that are interspersed with long glides.

WRIA 57 Reach (RM 72.3-73.8): The WRIA 57 Reach is low gradient, with well-defined banks. Long glides are the dominant habitat feature, with pools and wide riffles interspersed throughout the reach. Latah Creek marks the lower boundary of the WRIA 57 reach.

2.4 Physical Habitat Surveys

Physical habitat surveys were conducted with low elevation, high resolution aerial photographs and an on site field survey of the Spokane River from Nine Mile reservoir to the Monroe Street Bridge. The purpose of the survey was to obtain an overview of the river and determine the frequency of various types of fisheries habitat found within the study area.

The aerial photos, supplied by Avista Utilities, were used to characterize the habitat types throughout the Spokane River. Areas with a variety of habitat types located in a relatively short distance were noted as possible locations for transect placement. With the initial habitat characterization complete, the entire length of the Spokane River from Nine Mile reservoir to the Monroe Street Bridge was surveyed on foot in order to ground truth the initial habitat typing from the aerial photos. When necessary, habitat types were changed to match what was observed on the ground. A frequency distribution of habitat types formed the basis for transect weighting. Details of the habitat frequency analysis are described in Section 2.6.

2.5 Transect Selection

Study sites and transects were selected to represent the variety of habitat types within the Spokane River (Table 2.6-2). EESC selected 7 transects within the 2 study reaches between the Monroe Street Bridge and Nine Mile Reservoir. The study sites and transects were approved by representatives of the Department of Ecology and WDFW during a site visit on March 29, 2006. Figures 2.5-1 and 2.5-2 show locations of study sites and transect locations throughout the Spokane River Study Area.

During the site visit, WDFW representatives requested photo documentation of riffle habitat at several locations in the study area. The reason for the photographs was to visually compare the effect of streamflow on the riffle habitat. Photo sites were selected at 3 different locations:

- Upstream and downstream of the Centennial Foot Bridge
- Up stream of the T.J. Meenach Bridge
- Downstream of the Gun Club

Staff from the Spokane County Public Works Department took photographs at various river flows. See section 1.2 for additional details and Appendix D for presentation of the photographs.

2.6 Transect Weighting

Habitat mapping transects were drawn on aerial photographs (1:1,200), every 300 feet. All mapped transects were viewed in the field at a flow of 2,500 – 3,000 cfs. Each transect was compared to the PHABSIM modeling transects and was tallied under the PHABSIM transect that was most similar. Criteria used for discriminating between transects were width, depth, velocity, slope and substrate. The number of transects tallied under each PHABSIM transect was divided by the total number of mapping transects for each WRIA. WRIA 57 and WRIA 54 transect weighting was done separately and based on the total number of mapping transects in each WRIA. In WRIA 54, a few mapping transects that occurred in white water habitat near the Bowl and Pitcher and the Devils Toenail were not tallied since no PHABSIM transects had conditions that were similar.

Thirty three mapping transects were located in WRIA 57 (Monroe Street Bridge to Latah Creek). Forty one percent of the transects were similar to Transect 1 and 59% were comparable to Transect 2.

One hundred and thirty six (136) habitat mapping transects were located on aerial photographs, viewed and categorized on the Spokane River in WRIA 54 (Latah Creek to Nine mile reservoir backwater, located just downstream of the Gun Club). The transect weighting was based on the proportion of mapping transects similar to each of the calibration transects.

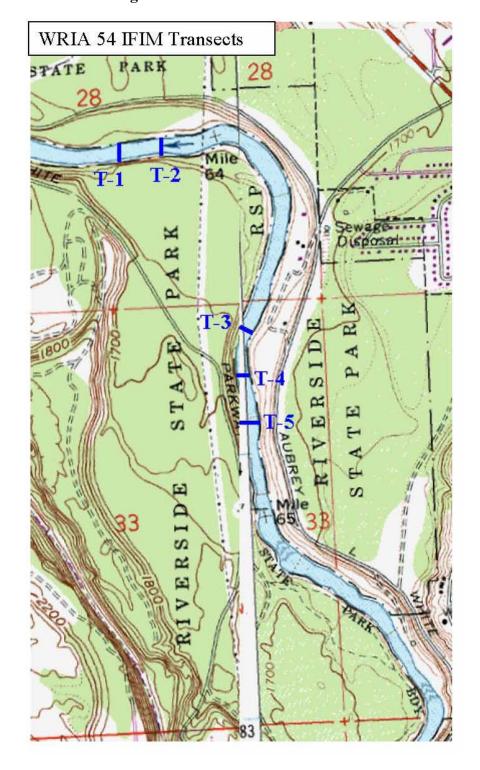

Figure 2.5-1 WRIA 54 IFIM Transects

Figure 2.5-2 WRIA 57 IFIM Transects

	Table 2.6-1 Macrohabitat Type and Descriptions								
Habitat Name Habitat Description									
Backwater/Eddy Pool	Upstream of flow obstruction or on channel margins where flow decelerates. Slower velocity and deeper, non-turbulent flow with a strong hydraulic control. Often fine particles due to reduced shear stress. Water surface slope <1%.								
Lateral pool	Pool formed on the margin of the stream as a result of a structural element, substrate composition, or thalweg location. (Generally at least ½ of the pool perimeter interfaces with adjacent habitat units.)								
Glide	Smooth generally unbroken surface, generally laminar flow, moderate to shallow depth, often smaller substrates. Often doubles as a pool tailout.								
Run	Deeper with fast to moderate velocities (more than a glide), lateral bottom profile normally uneven, surface is broken and often turbulent. Poorly sorted substrate upstream of obstructions.								
Riffle	Topographic crossover between pool and bar in pool-riffle morphology; spans the channel; particles are usually fairly well-sorted; water surface slope 1-4%								
Side channel	Small channel relative to main channel; may or may not have flow at time of survey; includes remnant flood terrace side channels that can often be vegetated.								
	Note: Habitat types may change as flow changes and comparisons for transect weighting were all made at nearly the same flow of $2,500 - 3,000$ cfs.								

	Table 2.6-2 Spokane River Transect Weighting								
Transect No.	Transect Description	Transect Weight							
Reach 57									
1	Run, shallower, wider and faster than Transect 2.	41%							
2	Smooth glide, laminar flow. Higher velocities on right bank	59%							
Reach 54	Mid Width Glide. Downstream of Rifle Club	29.4%							
1	Pool/Glide Complex. Downstream of Rifle Club	27.2%							
2	Med Fast Run, faster water all across transect	16.2%							
3	Medium Run. Slightly faster on left bank	11.8%							
4 5	Glide/ Run transition. 50/50 each habitat type	15.4%							

2.7 Field Methods

Mainstem Spokane River

The field methods and hydraulic analysis for the mainstem Spokane River followed the 1-velocity method as described in Payne (2003). This method uses one set of velocity measurements and a water surface elevation (WSE), usually at the high flow, and two additional stage discharge points (WSE) as input to the PHABSIM model to generate hydraulic simulations for the desired range of flows at each transect. The EESC field team obtained a high flow set of

hydraulic calibration measurements at each transect. Measurements included depths and velocities at close intervals across the transect and water surface elevations at each transect at each of the three flows. See section 2.11 for additional details of the PHABSIM modeling.

Mid-channel depth and velocity distributions at the calibration flow were measured using an acoustic doppler current profiler (ADCP) mounted on a small trimaran boat and side-tied to a jet boat. The ADCP records real time water temperature and uses temperature calibrated acoustic pulses to measure water velocities and depths across the channel. According to an extensive evaluation conducted by the U.S. Geological Survey (USGS), "ADCP's can be used successfully for data collection under a variety of field conditions" (USGS 1996). ADCP hydraulic measurements are made from a boat by moving the ADCP across the channel while it collects vertical-velocity profile and channel-depth data. The ADCP tracks the distance traveled from the point of origin so each depth and velocity measurement is coordinated with a horizontal distance on the transect. Measurements are taken at close intervals across the transect and at multiple levels in the water column. The ADCP is connected by cable to a power source and a radio modem that is linked to a laptop computer on shore. The computer is used to program the instrument, monitor its operation, and collect and store the data.

Because the ADCP will not measure in depths less than approximately 1.5 feet, shallow depth measurements near shore and other locations were taken manually using a Swoffer brand, propeller-type velocity meter mounted on a standard top-set USGS wading rod. Manually measured velocities were taken at sixth tenths of the depth when depths were less than 2.5 feet and at two tenths and eight tenths of the depth when depths equaled or exceeded 2.5 feet or when the expected velocity profile was altered by an obstruction immediately upstream.

An auto level was used to measure headpin elevations (the end point of each transect), water surface elevations (WSE), hydraulic controls and above water bed elevations along each transect. All measurements were referenced relative to a temporary benchmark. Bed elevations below the water surface were obtained by subtracting measured depths taken during velocity calibration from the water surface elevations for that particular transect. Except when surveying the bed profile, the surveyor attempted to measure elevations to the nearest .01 feet.

Substrate and cover were measured visually during a low flow period in September. In the deeper portions of pool transects substrate was measured with the aid of a mask and snorkel. Substrate was classified using a three-digit code representing the most abundant particle size, the second-most abundant particle size, and the percentage of the most abundant particle size. For example, a code of 73.7 would mean that the most abundant substrate was large cobble (6 to 12-inch diameter), that small gravel (0.5 to 1.5-inch diameter) was the second-most abundant substrate, and that large cobble represented 70 percent of the cell area. Cover and substrate codes are shown in Appendix A and are referenced from the revised Washington State Resource Agency Instream Flow Guidelines (WDFW/Ecology, 2004).

Spokane River Tributaries

Upon agreement with the Spokane River Instream Flow Technical Team (IFTT), instream flow assessments on four Spokane river tributaries were conducted using the Toe-Width method

(Swift 1976). The four streams selected for assessment were Coulee, Deep, Spring, and Little Chamokane creeks. The Spokane Tributaries Toe-Width assessment is presented in Appendix C of this report.

2.8 Affected Species and Life Stages

Fisheries resources of primary concern in the Spokane River are rainbow trout and mountain whitefish. These species were identified as the principal species of concern for WRIA 54 and 57 by WDFW and this decision was supported by the IFTT and the Planning Unit. Both species utilize the study area during a significant portion of their life cycle. In a letter dated February 8, 2007 WDFW recommended that rainbow trout and mountain whitefish receive equal weighting when considering Spokane River instream flow needs. Figure 2.8-1 presents the life stage timing of target species in the Spokane River.

2.9 Habitat Suitability Criteria

Fish are not found randomly in streams and rivers, but rather have preferences for particular ranges of depth, velocity, cover and substrate. These preferences vary depending on species and life stage. In PHABSIM studies, the ranges of each of these parameters are commonly referred to as fish preference criteria or a Habitat Suitability Criteria (HSC).

Habitat Suitability Criteria for the Spokane River PHABSIM study for rainbow trout were recommended by the Washington Department of Ecology and Washington Department of Fish and Wildlife (WDFW/Ecology, 2004). Washington State data from many studies, over several years have been combined to form a comprehensive data set. In the absence of site specific data for each PHABSIM study, this Washington "standard" HSC is used. The HSC tables used for the Spokane PHABSIM study are contained in Appendix A to this report. Rainbow Trout life stages to be modeled are;

- Spawning
- Juvenile/Adult Rearing
- Winter Rearing

No HSC data for Mountain Whitefish are published in the Washington State Instream Flow Guidelines. After consultation with Hal Beecher, WDFW Instream Flow Biologist, habitat suitability criteria for Mountain Whitefish will be the same as used for the Little Spokane River Instream Flow Study for WRIA 55. Mountain Whitefish life stages to be modeled are;

- Spawning
- Fry
- Juvenile Rearing
- Adult Rearing

Figure 2.8-1
Spokane River Fish Periodicity

Species	Lifestage	Oct	Nov	Dec	Jan	Feb	Mar	April	May	June	July	Aug	Sept

Blank areas indicate periods of little or no use

2.10 Data Compilation Methods

The ADCP interfaces directly with a laptop computer when collecting data. Software provided by RD Instruments, manufacturer of the ADCP, is used to record and display the data in real time as it is collected. This output of this program is a text file which contains transect details, including depth (ft), velocity (ft/sec), distance (ft), and error checking values for each vertical and bin along the transect. Verticals are columns looking straight down from the water surface to the river bottom at measured distances from the starting point. Velocity data taken at incremental depths at each vertical are called bins.

EESC used Riverine Habitat Simulation (RHABSIM) by Thomas R. Payne and Associates, Arcata, CA to model the Spokane River flows. RHABSIM is a PC conversion and enhancement of the original PHABSIM suite of hydraulic and habitat modeling software developed by the U.S. Fish and Wildlife Service. A conversion utility from RHABSIM allows the ADCP data to be imported into a spreadsheet. This utility screens out errors and converts bins of velocities into mean column velocities (average velocity in ft/sec for each vertical). Three summary columns are created:

- Distance from the beginning of the transect
- Depth
- Mean column velocity of each vertical

The ADCP cannot take measurements in shallow water (under 1.5 feet). As a result, field staff from EESC took manual depth and velocity measurements along each bank where the depths were too shallow. The manual measurements taken along each river bank, the ADCP data, and substrate and cover values were entered into a spreadsheet. Depths were converted into elevations (ft) by subtracting the measured depth from a surveyed water surface elevation. A total discharge for each transect was then calculated. At this point the data for each transect was subjected to a final check for errors and corrected. The corrected data files were then converted into a format readable by RHABSIM. RHABSIM read the file, and the completed data deck was ready for model calibration.

2.11 Data Analysis

2.11.1 Hydraulic Modeling

Analysis and integration of physical stream measurements and habitat preference criteria require the use of a group of the RHABSIM computer programs. There are two main programs in the RHABSIM library: the hydraulic model (called HYDSIM) and the habitat model (called HABSIM).

Hydraulic modeling involves two sequential steps. The first step, a short version of what the USGS does to rate a stream gauge, is to develop a stage-discharge relationship, and the second stage is velocity calibration. The stage is the height of the water surface at a location (in this case at each transect). At several (at least 3) widely separated (lowest flow should be half or less of the next highest flow) calibration flows, stages and flows should be measured and recorded.

These can be graphed on logarithmic scale and will yield a (relatively) straight line and a regression equation can be fit to the line. The regression equation then predicts the water surface height (and, by subtraction, the depth, when bed elevation at different locations are known) at different flows from what were measured at the calibration flows. At each point along a transect, velocity calibration is needed to estimate velocity. An average velocity for the river can be calculated at a transect if flow and the cross-sectional area of the river is known at the transect.

Flow (Q, in cubic feet per second) = cross-sectional area (A) x average velocity (V), and A=depth x width; thus V = Q/A.

Velocity calibration allows fine-tuning of velocity distribution across a transect; it is not uniform, but faster in some places and slower in others. Over a range of flows it is possible to modify (either increase or decrease) the "cell" velocity relative to the average velocity by using measured velocity to indicate relative resistance to flow or roughness. Successful velocity calibration generates reasonable approximations of the local velocities. Other velocity calibration methods are also available. Overall, the Washington Department of Fish and Wildlife approves the calibration approach used in this technical report.

The HABTAT program integrates the simulated hydraulic information from HYDSIM with habitat suitability criteria (i.e., preference or HSI curves) and quantifies habitat availability over a range of flows for the specified target species and life stages. Habitat quantification is expressed as an index called Weighted Useable Area (WUA), and is given in units of habitat per 1,000 linear ft of stream.

2.11.2 Hydraulic Modeling Procedures

EESC calibrated the Spokane River hydraulic model using methods described in Payne (2003). All of the input decks were initially processed using the Problem Report subroutine of the Field Data Entry Module of RHABSIM. This program looks for errors in data placement and produces a hard copy of the pertinent information needed to run the model, including transect weighting factors, slopes, stage of zero flow and WSE. EESC collected one set of velocity calibration measurements at each transect at the high calibration flow. In addition to the high flow calibration flow, a WSE at each transect and a discharge measurement at each study site at the two lower flows were used to generate the stage-discharge relationship.

In Washington State, a standard "three velocity set" regression model is often used on all transects. The three-velocity set models require that verticals be placed in exactly the same locations along the stream bed and that velocity measurements be taken at these verticals at all three calibration flows. The data collection for a three velocity set model is time consuming and very expensive in any stream or river that is not wadeable at all calibration flows.

A less expensive, yet good approach is the use of a "one velocity set" model. "One velocity set" models use the velocities from one of the calibration flow measurements for velocity modeling and employ the WSE's from the other calibration flows to develop the stage/discharge relationship. After discussions on PHABSIM analysis with representatives from WDFW and

Ecology, all parties agreed that a "one velocity set" modeling approach would be appropriate for use at the Spokane River transects.

One of the goals of the hydraulic simulation is to have the model accurately reflect measured velocities and depths at calibration flows, while minimizing changes to the data. In this regard, only minor changes were made to the IFIM decks in order for the model to more accurately predict cell velocities at the simulated flow. When calibrating one velocity set data decks, normally, two types of corrections can be made directly or indirectly to velocity data: 1) changes in the measured velocity; and, 2) changes in the Manning's N (roughness coefficient) for given cells. Changes were kept to a minimum and the decks were revised only when specific changes improved model performance.

One type of data change was a minor velocity adjustment (0.01 - 0.10 ft/sec) in some cells where there was a measured depth but no measured velocity. The model interprets a measured zero velocity as a blank and will attempt to fill that cell with a velocity based on a mass balance equation for the transect, taking into consideration slope, adjacent velocities, and calculated Manning's N values. Replacing a measured 0.00 with a velocity of 0.01 or 0.1 often corrects this problem. In addition, edge cells are often assigned high Manning's N values (i.e., the roughness coefficient) by the model. The high N values slow the velocity through these cells, giving an unrealistic simulation of velocities. In these instances the N values were manually reduced.

The range of extrapolation for simulated depths and velocities depends on the hydraulics of the channel and the spread between calibration flows. When using one velocity set models, the accuracy of the velocity simulation, slope and Manning's N values are considered. In the case of one velocity set models, the Velocity Adjustment Factors (VAFs) are adjustment factors of discharge, not velocities, and a wider range of values (between 0.10 and 10.0) is acceptable. A summary of VAFs and calibration details are presented in Tables 2 and 4 of Appendix B. Flows of interest were within the limits of acceptable extrapolation.

2.11.3 Measured Flows for the Spokane River

A single set of calibration flow data was developed from the field measurements. Actual measured flows for the Spokane River are shown in Table 2.11-1.

Table 2.11-1 Calibration Flows (cfs), Spokane River, WRIA 57 & 54								
	High Flow And Velocity Calibration 6/23/2006							
WRIA 57 Discharge (cfs)	867	2,681	6,225					
WRIA 57 Water Temp (degrees F)	62	69	62-63					
WRIA 54 Discharge (cfs) T1 & T2 870 cfs on 9/12/06	1,069	3,157	6,328-6,970					
WRIA 54 Water Temp (degrees F)	59-60	65	62					

2.11.4 Model Performance

Only minor changes were made to the original input decks. Most revisions fell into three categories:

- Replacing a measured velocity of 0.0 ft/second with a velocity of 0.1 ft/second
- Changing the Manning's N value to either reduce or increase the velocities in the given cell
- Adjusting the bed elevations at the stream margin cells slightly

Appendix B summarizes calibration details for each transect. Mean error of the stage/discharge relationship, ratio of measured vs. predicted discharges, and B coefficients were all within the acceptable limits for PHABSIM calibration.

Output from the calibrated hydraulic models was then used to simulate water depths and velocities in the Spokane River throughout a range of flows from 350 cfs to 16,000 cfs.

After the hydraulic models were calibrated, transect weighting and lengths to simulate a 1,000 foot reach were added as shown in Table 2.6-1 and 2.6-2. Final hydraulic model runs were made to produce input for the HABTAT habitat model. These hydraulic runs were then combined with habitat suitability criteria for both spawning and rearing life stages of the target species to calculate WUA.

3.0 RESULTS

Within the HABTAT program, output from the hydraulic modeling is combined with habitat suitability criteria (HSC) for depth, velocity, and substrate/cover for the target species life stages. The output from this model is expressed as Flow (Q) in cubic feet per second (cfs) vs. Weighted Usable Area (WUA), which is an index of available habitat per 1,000 lineal ft of stream, for each species and life stage of concern.

WUA incorporates the hydraulic variables of width, depth, velocity, slope, substrate and cover measured in the Spokane River with the habitat needs of each species and illustrates how the habitat for each species varies with changes in flow. The hydraulics are largely influenced by the shape of the river channel with narrower channels exhibiting increased velocity that may limit available habitat for the target fish species.

3.1 Weighted Usable Area Results

Figures 3.1-1 and 3.1-2 show Spokane River Flow vs. WUA graphs for WRIA 57 rainbow trout and mountain whitefish rearing and spawning life stages. Figures 3.1-3 and 3.1-4 show Spokane River Flow v WUA graphs for WRIA 54 rainbow trout and mountain whitefish rearing and spawning life stages. Tables 3.1-1 to 3.1-4 give tabular results of the Spokane River WUA data.

3.2 Measured Water Temperature

Water temperature was measured and recorded by the ADCP at each measured discharge at each Study Site. Table 2.11-1 shows water temperature measurements at each location.

4.0 HYDROLOGY

The Spokane River gage at Spokane has a long-term record that provides a solid hydrological display of the runoff pattern. Although the Spokane gage gives a very good record of flow for WRIA 57, the inflow from Latah Creek and ground water accretion to the river throughout WRIA 54, contributes a substantial quantity of water which is not measured at the gage. During the summer low flow months, Latah Creek flows are generally low while ground water can add 30% to the flow between the Spokane gauge and the Gun Club. This accretion was documented by the Washington Department of Ecology and USGS on August 30, 2005 when 613 cfs was measured at the Spokane gage and 797 cfs was measured at the Gun Club. Spokane River flows from the August 30, 2005 accretion measurements are shown in Table 4-1. Low flow discharge comparisons based on EES measurements at the Spokane River at Spokane gauge on August 14th and Spokane River at Gun Club on August 15th, 2006 are not exactly comparable, but reinforce the case for significant inflow between the two sites. Discharges at the Spokane gauge were 867 cfs while 1 day later discharges at the Gun Club were 1,069 cfs.

Table 4-1 2005 Accretion Flows								
Location	Date	Discharge (cfs)						
Spokane R at Spokane	8/30/2005	613						
Hangman Cr at Spokane	8/30/2005	1.5						
Spokane R blw TJ Meenach B	8/30/2005	703						
Spokane R at Gun Club	8/30/2005	797						
Deep Creek nr Confluence	8/29/2005	0.0						
Spokane R blw Nine Mile Dam	8/30/2005	938						

Streamflow from the mountainous regions of the Spokane basin is highest from April through June, averaging 160%-265% of the 6,685 cfs mean annual flow (MAF) as snowmelt fills the streams for an extended period. August and September are generally the lowest flow months of the year with an average discharge of just 26% of MAF. The timing and duration of the spring runoff is strongly influenced by snowpack, day length, air temperature and wind. During the fall and winter months streamflow is influenced by fluctuating freezing levels and rainfall. Fall and winter flows are generally moderate, averaging approximately 50%-100% of MAF.

Avista Utilities operates the Spokane Hydroelectric Project (FERC No. 2545), which has project components both upstream and downstream of the WRIA 54 and 57 study reaches, but not within this the study area. Although Avista generally operates the hydroelectric project on a near run-of-river basis, water is seasonally stored and released from Lake Coeur d'Alene by a dam located upstream of Spokane in Post Falls, Idaho.

The annual hydrograph for the Spokane River at Spokane (1891- 2004) is presented in Figure 4-1. In comments on the Draft report, several Planning Unit members noted that since 1968 water operations in the Spokane River have changed. Figure 4-2 illustrates the annual hydrograph utilizing only records from Water Year1968 – 2005.

5.0 DRAFT RECOMMENDATIONS

Instream flow recommendations best serve the community when they are based on shared objectives and are part of a carefully planned and considered water resource strategy. Essential elements of a water strategy would likely include instream flows, a water reservation exempt from instream flow, a maximum allocation that would set limits on the total amount of new water withdrawal at any given time, as well as other issues critical to Planning Unit members. Since neither objectives to guide instream flow setting, nor essential elements of a water resource strategy have been articulated, these instream flow recommendations, based on fish habitat preferences, should serve as the guidelines for discussion on this topic.

5.1 Balancing Needs Of Target Species

Initial information provided by fisheries biologists from WDFW and the Spokane Tribe indicated that habitat for both Rainbow Trout and Mountain Whitefish is important in the Spokane River and should be assessed in the current instream flow study (WDFW IFTT Recommendations, 2006). Further consultation has refined these recommendations and led to the suggestion that habitat needs of the two species be balanced on an equal basis (WDFW letter February 7, 2007).

Figures 5-1 and 5-2 show all of the life stages, for both species, on a single graph each for WRIA 57 and 54 respectively. Although somewhat busy, these graphs illustrate the gains and losses for each species and life stage as flows change.

It should be noted that peak WUA for each species generally occurs at a higher flow in the upstream Spokane River in WRIA 57 rather than downstream in WRIA 54. Although somewhat counterintuitive, wetted river channel in WRIA 57 is generally wider than in WRIA 54. The wider channel provides a greater area for the flow to spread out and habitat to be created as discharge in the river increases.

To facilitate evaluating the combined habitat results for both rainbow trout and mountain whitefish, two different comparisons of the data were made. For the first comparison the following computations were completed.

- The percent of peak WUA for the adult lifestage of whitefish and the juvenile/adult lifestage of rainbow were summed.
- A new "peak" WUA of this combined total was identified and all results were recomputed as a percent of this new peak.
- Results of this comparison are shown in Tables 5.1 and 5.2 for WRIA's 57 and 54 respectively. Peak percent for this comparison is shaded in gray.

Although the above comparison numerically balanced habitat for both species, the highest combined numbers resulted in a much higher percent habitat loss for whitefish than for rainbow trout. The second analysis attempts to more equally balance the habitat loss for each species. Tables 5.1-1 and 5.1-2 highlight in green the flows where the percent of peak habitat for each species is between 80% and 90%.

5.2 Example Draft Instream Flow Recommendations

Recommendations in this draft report are general in nature and cover a range of possible objectives. The WRIA 54 and 57 Planning Units are best suited to formulate clear objectives and develop details of a comprehensive water resources plan which, for each watershed, will address the full range of water issues including instream flow. Table 5.2-1 illustrates how instream flow recommendations could vary given the range of objectives the planning units could adopt related to different priorities for protecting fish habitat. The purpose of this instream flow study was to show how the habitat for the selected species changes with changes in flow. None of the recommendations shown are likely to be "right". Rather they are based on the following subjective criteria that planning unit members may choose to consider in their instream flow deliberations.

- Criteria 1 The priority objective is protection of habitat for combined species.
- Criteria 2 The priority is maximum ability and flexibility to withdraw water while limiting effects on fish habitat.
- Criteria 3 Both future water use and protecting fish habitat are important and reflected in instream flow setting.

The instream flows that follow these objectives are primarily based on the results of the Spokane River PHABSIM Study discussed in this document and the rainbow trout spawning analysis conducted below Monroe Street by Northwest Hydraulics and Hardin-Davis (2004). Additional data, including hydrologic records, results of ground water inflow studies and additional analysis may produce different results.

Below is a key listing the basic rationale for the individual recommendations. Timing for each species and lifestage reflects the individual fish periodicity from Figure 2.8-1. Spawning was given priority over rearing. Rearing for adults was given priority over fry and juveniles.

F	<u> </u>	Covers 80% - 90% of peak rearing habitat for each species
E	8	Maximum spawning habitat for affected species
		Maximum rainbow& white fish combined rearing habitat
Ι)	2/3 of maximum spawning habitat for affected species
E	3	Incubation at 2/3 of spawning flow
F	7	90% of peak spawning habitat for affected species
